Received 2018 September 4; accepted 2018 October 31

Abstract The success of LISA Pathfinder in demonstrating the LISA drag-free requirement paved the road of using space interferometers to detect low-frequency and middle-frequency gravitational waves (GWs). The TAIJI GW mission and the new LISA GW mission propose to use arm length of 3 Gm (1 Gm = 10^6 km) and arm length of 2.5 Gm respectively. For space laser-interferometric GW antenna, due to astrodynamical orbit variation, time delay interferometry (TDI) is needed to achieve nearly equivalent equal-arms for suppressing the laser frequency noise under the level of the optical path noise, acceleration noise etc for attaining the requisite sensitivity. In this paper, we simulate the TDI numerically for TAIJI mission and the new LISA mission. To do this, we work out a set of 2200-day (6-year) optimized science orbits of each mission starting at March 22, 2028 using the CGC 2.7.1 ephemeris framework. Then we use the numerical method to calculate the residual optical path differences of the first-generation TDI configurations and the selected second generation TDI configurations. The resulting optical path differences of the second-generation TDI configurations calculated for TAIJI (except the [\(a^2b^2\), \(b^2a^2\)] series TDIs which are marginal), new LISA, and eLISA are well below their respective requirements for the laser frequency noise cancellation. However, for the first generation TDI configurations, the original requirements need to be relaxed by 3 to 30 fold to be satisfied. For TAIJI and the new LISA, about one order of magnitude relaxation would be good and recommended; this could be borne on the laser stability requirement in view of recent progress in laser stability, or the GW detection sensitivities of the second generation TDIs have to be used in the diagnosis of the observed data instead of the commonly used X, Y, and Z TDIs.

Key words: gravitational waves — methods: numerical — techniques: interferometric

1 INTRODUCTION AND SUMMARY

GW detection has been a focused subject of research for several decades. In all GW frequency bands, detection efforts are pursued vigorously (See, e.g. Kuroda et al. 2015). With the announcement of advanced LIGO and Virgo direct gravitational wave (GW) detection (Abbott et al. 2016b,a, 2017a,c,d,b), we are in the age of GW astronomy.
1.1 Space laser-interferometric GW detectors

Space laser-interferometric GW detectors operate in the low frequency band (100 nHz–0.1 Hz) and the middle frequency band (0.1 Hz–10 Hz). The scientific goals are to detect following GW sources in these bands: (i) Massive black holes (BHs); (ii) Extreme mass ratio inspirals; (iii) Intermediate-mass black holes; (iv) Compact binaries; (v) Relic GWs, and to use observation and measurement of these sources to study the co-evolution of massive BHs with galaxies, to anticipate binary merging GW events in the high frequency band (10 Hz–100 kHz) for Earth-based GW detection, to test relativistic gravity, to determine cosmological parameters, and to study dark energy equation of state. Space-borne GW detectors may provide much higher signal-to-noise ratio for GW detection than Earth-based detectors.

Interferometric GW detection in space basically measures the difference in the distances traveled through two routes of laser links among spacecraft (S/C) or celestial bodies as GWs come by. The S/C (or celestial bodies) must be in geodesic motion (or such motion can be deduced). The distance measurement must be ultra-sensitive as the GWs are weak. Therefore, the drag-free technology to guarantee the geodesic motion and laser stabilization to ensure the required level of measurement are essential to achieve the scientific goals. On the other hand, due to the long distance between spacecraft in space GW missions, the appropriate amplification method between laser links is also crucial to do the measurement. And this is achieved by either homodyne or heterodyne optical phase locking the local oscillator to the incoming weak light at the received link.

Launched on 3 December 2015, LISA (Laser Interferometer Space Antenna) Pathfinder (Armano et al. 2016), has completely met the stringent LISA drag-free demand (Amaro-Seoane et al. 2017), and has demonstrated the drag-free technology successfully for space detection of GWs.

Liao et al. (2002b,a) and Dick et al. (2008) have demonstrated homodyne phase-locking to 2 pW incoming weak light and offset phase locking to 40 fW incoming laser light respectively. Gerberding et al. (2013) and Francis et al. (2014) have recently phase-locked a 3.5 pW light signal and a 30 fW light signal respectively. LISA requires 85 pW laser light phase locking. Hence, the locking power requirement is demonstrated in laboratories. Frequency-tracking, coding-decoding and modulation-demodulation need to be well-developed in the future to make it a mature technology.

To reach the measurement sensitivity goal for space detection, we need to suppress spurious noise below the aimed sensitivity level. This requires us to reduce the laser noise as much as possible. The drag-free technology is now demonstrated by LISA Pathfinder. Nevertheless, the best laser stabilization alone is not currently enough to reduce directly the laser noise in the required strain sensitivity of $10^{-21}$. To lessen the laser frequency noise requirement, time delay interferometry came to rescue.

1.2 Time delay interferometry (TDI)

For drag-free spacecraft, the interferometric arm lengths vary according to astrodynamics. Laser noise must be suppressed below other noises as the optical path noise, the acceleration noise etc to attain the requisite sensitivity. For suppressing laser frequency noise, TDI is necessary to be used to match the optical path length in different beam paths closely in the analysis.

Except for DECIGO (Kawamura et al. 2006, 2011) whose arm lengths are controlled, all other space-borne GW interferometers have their arm lengths vary geodetically (in free fall) according to orbit dynamics. The TDI technique is to use two different optical paths with sufficiently close optical path lengths and follow them in opposite/different order. This way the laser frequency noise is suppressed when optical path lengths (time travelled) of the two paths are close enough.

Ni et al. (1997); Ni (1997) first used TDI to study ASTROD mission concept in the 1990s numerically using Newtonian dynamics. The two TDI configurations are the unequal arm Michelson TDI configuration and the Sagnac TDI configuration for three spacecraft. The principle is to have two split laser beams to go to Paths 1 and 2 and interfere at their end of the paths. For the unequal arm Michelson TDI configuration, the 2 paths are

$$\text{Path 1 : S/C1} \rightarrow \text{S/C2} \rightarrow \text{S/C1} \rightarrow \text{S/C3} \rightarrow \text{S/C1},$$

$$\text{Path 2 : S/C1} \rightarrow \text{S/C3} \rightarrow \text{S/C1} \rightarrow \text{S/C2} \rightarrow \text{S/C1}. \quad (1)$$
In the Sagnac TDI configuration, the two paths are:

\[
\begin{align*}
\text{Path 1: } & S/C_1 \rightarrow S/C_2 \rightarrow S/C_3 \rightarrow S/C_1, \\
\text{Path 2: } & S/C_1 \rightarrow S/C_3 \rightarrow S/C_2 \rightarrow S/C_1.
\end{align*}
\] (2)

After that we have performed the numerical simulation of the TDI using post-Newtonian ephemeris for ASTROD-GW with no inclination (Wang & Ni 2012, 2013b), LISA (Dhurandhar et al. 2013), eLISA/NGO (Wang & Ni 2013a), LISA-type with 2 Gm arm length (Wang & Ni 2013a), and ASTROD-GW with inclinations (Wang & Ni 2015).

These two configurations are first-generation in the sense of Armstrong et al. (1999) for LISA. For a thorough discussion on the generations and other aspects of TDI, see Tinto & Dhurandhar (2014).

1.2.1 \(X, Y, Z, X+Y+Z\), Sagnac and other first-generation TDIs

The unequal arm Michelson TDI starting from S/C1 is frequently denoted by the symbol X. That starting from S/C2 with (1, 2, 3) permutation in spacecraft is frequently denoted by the symbol Y and the one starting from S/C3 by the symbol Z. The Sagnac configuration is frequently denoted by the symbol \(\alpha\), those with successive permutation(s) by the symbols \(\beta\) and \(\gamma\). We shall adopt this notation first used in Armstrong et al. (1999).

Following our previous work (Wang & Ni 2015) for the numerical evaluation, we take a common receiving time epoch for both beams to calculate the path differences; and in this case, the results would be very close to the calculations which we take the common sending time epoch. This way, we can start from Path 1 and propagate the laser light to the end of Path 1 using ephemeris framework, and at the end point of Path 1, evolve laser light back in time along the reversed Path 2 to find the difference in the optical path length. In the TDI, we actually compare the laser signal this way. The results of this calculation of the first-generation TDI for various orbit configurations are shown in Fig. 5-8 in section 3, and their min, max and rms path length differences for a period of 2200 days are compiled in Table 1 of this section; those for the second-generation are shown in Fig. 9-12 in section 4 and the min, max and rms path length differences are compiled in Table 2. To be concise to denote the second-generation TDIs, the path S/C1 \(\rightarrow\) S/C2 \(\rightarrow\) S/C1 is notated as \(a\) and the path S/C1 \(\rightarrow\) S/C3 \(\rightarrow\) S/C1 is notated as \(b\) as done in Dhurandhar et al. (2010, 2013), and in Wang & Ni (2013a,b, 2015). Therefore, the difference \(\Delta L\) between Path 1 and Path 2 for the unequal-arm Michelson X could be denoted as \(ab - ba \equiv [a, b]\).

To extend this notation to the cyclic permuted paths, we refer to the path S/C2 \(\rightarrow\) S/C3 \(\rightarrow\) S/C2 as \(c\), the path S/C2 \(\rightarrow\) S/C1 \(\rightarrow\) S/C2 as \(d\), the path S/C3 \(\rightarrow\) S/C1 \(\rightarrow\) S/C3 as \(e\), and the path S/C3 \(\rightarrow\) S/C2 \(\rightarrow\) S/C3 as \(f\).

Unequal-arm Michelson (X, Y, Z), Sagnac (\(\alpha, \beta, \gamma\)), Relay (U, V, W), Beacon (P, Q, R), and Monitor (E, F, G) configurations are the first-generation TDIs which we calculate numerically in this paper. U, P, and E TDI configurations in geometric representation are given in Vallisneri (2005). They are drawn in Fig. 1 with spacecraft numbers. Two other configurations of each type having different spacecraft as initial points can be readily figured out by permutation.

1.2.2 Second-generation TDIs

There are many second-generation TDI configurations. In this work, we select \(n = 1\) and \(n = 2\) configurations which were obtained by Dhurandhar et al. (2010) assuming one detector with two arms for LISA. These configurations for S/C1 as the start point are listed as follows:

(I) \(n = 1, [ab, ba] = abba - baab\),
(II) \(n = 2, [a^2b^2, b^2a^2], [abab, babab], [ab^2a, ba^2b]\).
For S/C2 and S/C3 as the starts, the TDI configurations are respectively:

(III) \( n = 1, [ed, dc] \),
(IV) \( n = 2, [e^2d^2, d^2e^2]; [cdcd, dcde]; [ed^2c, dc^2d] \),
(V) \( n = 1, [ef, fe] \),
(VI) \( n = 2, [e^2f^2, f^2e^2]; [efeef, fefe]; [ef^2e, f^2e] \).

A second-generation TDI involves 3 arms is the following Sagnac-type TDI. From the first-generation Sagnac-\( \alpha \) configuration, we add another Sagnac-\( \alpha \) in reverse order to get a new interferometry path as follows:

Path 1: \( S/C_1 \rightarrow S/C_2 \rightarrow S/C_3 \rightarrow S/C_1 \rightarrow S/C_2 \rightarrow S/C_1 \),
Path 2: \( S/C_1 \rightarrow S/C_3 \rightarrow S/C_2 \rightarrow S/C_1 \rightarrow S/C_2 \rightarrow S/C_3 \rightarrow S/C_1 \).

We tag this interferometry configuration as \( \alpha 2 \) or Sagnac-\( \alpha 2 \). With cyclic permutations, we obtain the other 2 interferometry configurations \( \beta 2 \) and \( \gamma 2 \).

1.3 Orbit configuration for LISA-like missions

LISA was a mission proposed to ESA and NASA which would use laser links of a nearly equilateral triangle of side 5 Gm of three spacecraft to observe low-frequency GWs (LISA Study Team 2000). The formation would be inclined by about 60° with respect to the ecliptic trailing the Earth by about 20°, and rotate counterclockwise facing the Sun as shown in Fig. 2. This project ended nominally in April, 2011 with NASA’s withdrawal.

After the termination of ESA-NASA collaboration, a down-scaled LISA mission called eLISA/NGO was proposed from a joint effort of seven European countries (France, Germany, Italy, The Netherlands, Spain, Switzerland, and the UK) and ESA. The NGO assessment study report received excellent scientific evaluation (http://eLISA-ngo.org). The mission configuration consists of a “mother” S/C at one vertex and two “daughter” S/C at two other vertices with the mother S/C optically linked with two daughter S/C forming an interferometer. The duration of the mission is 2 years for science orbit and about 4 years including transferring and commissioning. The mission S/C orbit configuration is similar to LISA, but with a nominal arm length of 1 Gm, inclined by about 60° with respect to the ecliptic, and trailing Earth by 10°-20°.
1.4 TAIJI and the New LISA

Chinese Academy of Sciences initiated TAIJI program for pre-study of a GW detector in space in 2016 and chose a LISA-like formation with 3 Gm arm length to study (Hu & Wu 2017, Wu 2018, Guo et al. 2018).

On January 13th 2017, a new LISA proposal was submitted to ESA for the L3 slot of the Cosmic Vision Programme (Amaro-Seoane et al. 2017) and was selected in ESA’s Science programme. The basic concept is as the classical LISA with down-scaled arm length of 2.5 Gm. Quote from the proposal:

“...Three independent interferometric combinations of the light travel time between the test masses are possible, allowing, in data processing on the ground, the synthesis of two virtual Michelson interferometers plus a third null-stream, or ‘Sagnac’ configuration.”

The two Michelson interferometers are 2 TDIs. They could be X, Y or Z if the noise requirement is satisfied. Nevertheless, we will find out that these TDI’s do not meet the current noise requirement.

The TDI situation for TAIJI is similar as we will see in the next subsection.

1.5 Comparison of TDIs for interferometers with different arm lengths

In this paper, we use the CGC 2.7.1 ephemeris (See Wang & Ni 2015) to optimize the orbits and numerically evaluate TDIs. The differences in orbit evolution of Earth calculated using CGC 2.7.1 compared with that of DE430 starting at March 22nd, 2028 for 2200 days are less than 82 m, 0.32 mas and 0.11 mas for radial distance, longitude and latitude, respectively.

In Table 1, we compile and compare the resulting differences for the first-generation TDIs listed in the subsection 1.2.1, i.e. X, Y, Z, X+Y+Z and Sagnac configurations etc. of TAIJI, new LISA, classical LISA and eLISA. In Table 2, we compile and compare those for the second-generation TDIs listed in subsection 1.2.2.

From Table 1, all the first generation TDIs for LISA-like missions do not satisfy their respective requirements. From Table 2, all the second generation TDIs for eLISA and new LISA satisfy their respective requirements with good margins. For TAIJI, all the second generation TDIs satisfy their respective requirements with good margins, except the \([a^2b^2, a^2b^2a^2]\) series TDIs which barely violate the requirement. For classical LISA, the \([a^2b^2, b^2a^2]\) series TDIs and the \([abab, babab] \) series TDIs do not

satisfy the requirement while others do. To use the first-generation TDIs, requirement must be relaxed with accompanying technology development. To use the second-generation TDIs, the corresponding GW response and sensitivity must be calculated.

In section 2, we work out a set of 2200-day optimized spacecraft orbits starting at March 22, 2028 using the CGC 2.7.1 ephemeris framework for TAIJI, new LISA, classical LISA, and eLISA. In section 3, we obtain the numerical results pertaining to the first-generation TDIs for TAIJI and new LISA listed in Table 1. In section 4, we obtain the numerical results pertaining to the second-generation TDIs for TAIJI and new LISA listed in Table 2. In section 5, we compare and discuss in detail the resulting differences due to different arm lengths, and conclude this paper with discussion and outlook.

2 TAIJI, NEW LISA, ELISA AND CLASSICAL LISA ORBIT OPTIMIZATIONS

In the LISA-like missions, the distance of any two of three spacecraft must be maintained as close as possible during the geodetic flight to minimize relative Doppler velocities between spacecraft for satisfying respective Doppler frequency requirements. LISA orbit formation has been studied in various previous works (Vincent & Bender 1988; Folkner et al. 1997; Cutler 1998; Hughes 2002; Hechler & Folkner 2003; Dhurandhar et al. 2005; Yi et al. 2008; Li et al. 2008; Dhurandhar et al. 2013). We have used the CGC ephemeris framework together with initial conditions from DE ephemeris series to optimize the orbits of eLISA/NGO (Wang & Ni 2013a) and a LISA-type mission with 2 Gm nominal arm length (Wang & Ni 2013a) numerically, as well as that of ASTROD-GW (Men et al. 2010b,a; Wang & Ni 2011, 2012, 2013b).

The proposal of TAIJI (Hu & Wu 2017) and new LISA (Amaro-Seoane et al. 2017) chose as nominal arm lengths of 3 Gm and of 2.5 Gm, respectively. In this section, we describe the procedures of orbit choice and work out the optimization by taking the examples of the TAIJI proposal. After that, we work out the results for optimized orbits of new LISA, eLISA and classical LISA.
Table 2 Comparison of the resulting path length differences for the second generation TDIs listed in subsection 1.2.2 for 1 Gm (eLISA), 2.5 Gm (new LISA), 3 Gm (TAIJI), 5 Gm (classical LISA).

Nominal arm length: 1 Gm, 2.5 Gm, 3 Gm, 5 Gm
Mission duration (days): 2200
Requirement on ∆L: 10 m (33 ns), 25 m (83 ns), 30 m (100 ns), 50 m (167 ns)

2.1 The initial choice of initial conditions for TAIJI

There are various ways to choose the orbits of the three spacecraft so that the orbit configuration satisfying the equal arm length requirement to first order in $\alpha=\left[l/(2R)\right]$, the ratio of the planned arm length $l$ of the orbit configuration to twice radius $R$ (1 AU) of the mean Earth orbit. We follow the procedures given in Dhurandhar et al. (2005) and our previous paper Wang & Ni (2013a) to make initial choice of the initial conditions to start our optimization procedure.

We choose the initial time $t_0$ for science orbit configuration to be JD2462503.0 (2030-Jan-1st 12:00:00) and work in the heliocentric coordinate system $(X, Y, Z)$ with $X$-axis in the vernal equinox direction. First, a set of elliptical S/C orbits is defined as in Dhurandhar et al. (2005),

$$X_k = R(\cos \psi_k + \epsilon) \cos \epsilon$$
$$Y_k = R\sqrt{1 - \epsilon^2} \sin \psi_k$$
$$Z_k = R(\cos \psi_k + \epsilon) \sin \epsilon$$

where for the mission with nominal arm length $l$ equal $\lambda$ Gm, $\epsilon \approx 0.001925 \times \lambda$; $\epsilon \approx 0.00333 \times \lambda$; $R = 1$ AU. The eccentric anomaly $\psi_k$ is related to the mean anomaly $\Omega(t - t_0)$, and the $\Omega$ is defined as $2\pi/(\text{one sidereal year})$. The $\psi_k$ is defined implicitly by

$$\psi_k + \epsilon \sin \psi_k = \Omega(t - t_0) - (k - 1)\frac{2\pi}{3},$$

which is solved by numerical iteration. Define $x_k, y_k, z_k (k = 1, 2, 3)$ to be

$$x_k = X_k \cos \left[\frac{2\pi}{3}(k - 1) + \varphi_0\right] - Y_k \sin \left[\frac{2\pi}{3}(k - 1) + \varphi_0\right]$$
$$y_k = X_k \cos \left[\frac{2\pi}{3}(k - 1) + \varphi_0\right] + Y_k \sin \left[\frac{2\pi}{3}(k - 1) + \varphi_0\right]$$
$$z_k = Z_k$$

Numerical Simulation TDI for TAIJI and New LISA
where $\phi_0 = \psi_E - 20^\circ$ and $\psi_E$ is defined to be the position angle of Earth w.r.t. the X-axis at $t_0$. The initial conditions in the heliocentric coordinate are

$$\mathbf{R}_{S/C_k} = [x_k, y_k, z_k] \quad (k = 1, 2, 3) \quad (7)$$

Choosing $t = t_0$ we obtain the initial positions, and calculating the derivatives at $t = t_0$, we obtain the initial velocities. With the choice of $t_0 = JD2462503.0$ (2030-Jan-1st 12:00:00), the initially chosen orbits have relatively good equal-arm performance until JD2464053.0 (2034-Mar-31st 12:00:00). From the time trend of the performance, we perceived that the orbits would still be rather good when we back evolved the orbit for a period of time; and the result is as expected when the time goes back to JD2461853.0 (2028-Mar-22nd 12:00:00). Thereby, there could be a promising duration of 2200 days for optimization when the mission is set to start from JD2461853.0 (2028-Mar-22nd 12:00:00) with the evolved back initial conditions. For TAIJI, early launch would be desirable and GW observation starting in 2028 could be a possible scenario. For a 2030-start, this 2200 day orbit would also be useful as reference.

Our goal for the orbit optimization is twofold: (i) to equalize the three arm lengths as much as possible of the triangular formation and (ii) to reduce the Doppler velocities between 3 pairs of spacecraft. For the TAIJI proposal of 3 Gm arm length, the requirement on the Doppler velocities is below $\pm 6$ m/s between the S/Cs in order for frequency tracking between spacecraft to be within $\pm 6$ MHz (for laser light of 1064 nm wavelength) due to Doppler frequency shifts. For TDI, minimizing the Doppler velocities between the S/C also minimize the path length differences of various TDI configurations. We assume that the requirement on the Doppler velocities is directly proportional to the arm length. For example, for the classical LISA with arm length 5 Gm the requirement is $\pm 10$ m/s (LISA Study Team 2000). To accelerate our optimization program, Runge-Kutta 7th/8th order integration is used to search for the orbit in accordance with the mission requirement. The 4th order Runge-Kutta is used to verify stability after one candidate orbit is achieved.

### 2.2 The TAIJI mission orbit optimization

The goal of the TAIJI mission orbit optimization is to equalize the three arm lengths of the new LISA formation and to make the relative line-of-sight velocities smaller than 6 m/s between three pairs of spacecraft. Firstly, the initial conditions for the 3 S/Cs are calculated from the equations in section 2.1 at JD2462503.0 (2030-Jan-1st 12:00:00) and evolved back to JD2461853.0 (2028-Mar-22nd 12:00:00) using CGC 2.7.1 ephemeris framework. We list this initial choice of initial states in the third column of Table 3. The TAIJI spacecraft orbits are then calculated for 2200 days using CGC 2.7.1. The variations of arm lengths and Doppler velocities between the TAIJI S/Cs are drawn in Fig. 3.

As we can see in the Fig. 3, the Doppler velocity between S/C1 and S/C3 goes slightly beyond 6 m/s. The optimization procedure is to modify the initial heliocentric distances and/or velocities of the S/C. So we tentatively adjust the initial heliocentric distance of S/C1 to optimize the orbit. The optimized orbit was achieved when the heliocentric distance of S/C1 was decreased by a factor of $2.7\times10^{-7}$, and the initial conditions are shown in the fifth column of Table 3. The final achieved orbit’s variations of the arm lengths, Doppler velocities, the formation angles, and the lag angle behind the Earth with the mission time are shown in Fig. 4. The variations of arm lengths are within $\pm 1\%$ and velocities in the line of sight direction are within $\pm 6.0$ m/s requirement. The angle between barycentre of S/C and Earth in 2200 days starts at $22^\circ$ behind Earth and varies between $18^\circ$ and $23^\circ$ with a quasi-period of variation about 1 sidereal year due mainly to Earth’s elliptic motion.

### 2.3 The orbit optimization for new LISA, eLISA and classical LISA

For new LISA, classical LISA and eLISA with different arm lengths, the goal of the optimization is to make the Doppler velocities under a given prorated requirement as discussed in section 2.1, that is $\pm 5$ m/s, $\pm 10$ m/s and $\pm 2$ m/s respectively. In general, the shorter arm length the mission formation, the easier to achieve the optimization (since linear approximation works better). For the 1 Gm arm
Table 3 Initial states (conditions) of 3 S/C of TAIJI at epoch JD2461853.0 (2028-Mar-22nd 12:00:00) for our initial choice (third column) and after optimizations (forth column) in J2000 equatorial (Earth mean equator and equinox) solar-system-barycentric coordinate system.

length mission orbits, the initial conditions specified from the equations in subsection 2.1 with back evolution satisfy the requirement that the line-of-sight Doppler velocities be smaller than ±2 m/s for the period of mission considered. For new LISA, similar to TAIJI, the orbit configuration meets the mission requirement when the heliocentric distance of S/C1 is decreased by a factor of 3.0 × 10^{-7}.

With the increase of the arm length to 5 Gm, there are larger nonlinear perturbations on the variation of the arm length. More iterative adjustments are needed to meet the mission requirement. We adjusted the heliocentric distances of S/C1 and S/C2 together with the heliocentric velocity of the S/C1, before we achieve final optimized orbit. The scale of the adjustment is the order of 10^{-6} to 10^{-7} in the ecliptic heliocentric coordinate system. The optimized initial conditions for new LISA, classical LISA and eLISA are shown in Table 4.

The new LISA proposes the configuration lag angle behind the Earth to be around 20º while eLISA/NGO proposed the lag angle to be around 10º. This may make the orbits of the new LISA
Fig. 4 Variations of the arm lengths, the velocities in the line of sight direction, the formation angles, and angle between barycentre of S/C and Earth in 2200 days for the TAIJI S/C configuration with initial conditions given in column 5 (after optimization) of Table 3.

S/Cs suffer less gravitational perturbation from the Earth and the orbit configuration can stay stable for more than 6 years comparing to the orbit configuration of eLISA/NGO (Wang & Ni 2013a).

Since the initial condition choices for all missions worked out in this paper share the same epoch and nearly same barycenter of S/Cs, there could be some common features when we optimize this family which would be beneficial to our optimization process. We also believe that the optimized orbits we achieved in this paper are definitely not the only choices. These solutions just illustrate the possibilities and what we can achieve and assume. From our previous experiences and present investigation, there should be solutions at any epochs.

3 NUMERICAL SIMULATION OF THE FIRST-GENERATION TDI FOR TAIJI AND NEW LISA

In our early papers (Wang & Ni 2011, 2012), we have used the CGC 2.7 ephemeris framework to calculate the difference between the two path lengths for the first-generation TDI configurations of the planar non-precession ASTROD-GW orbit configuration. The results were shown by plotting the difference as function of the epoch of ASTROD-GW orbit configuration. The method of obtaining these solutions and the TDI configurations were briefly reviewed in section 1.2.

In the numerical calculation in this section, we calculate the difference between the two path lengths for TDI configurations and plot the difference as function of the signal arriving epoch of TDI in the first-generation TDI configurations — Michelson (X, Y, Z); Sagnac (\(\alpha, \beta, \gamma\)); Relay (U, V, W); Beacon (P, Q, R); Monitor (E, F, G) for TAIJI, new LISA. We use the iteration and interpolation methods (Chiou & Ni 2000, 2004; Newhall 1989; Li & Tian 2004) to calculate the time in the barycentric coordinate system as in our early papers. We do this for TAIJI in section 3.1, for new LISA mission in section 3.2.

3.1 Numerical results of the first-generation TDI for TAIJI

In this subsection, we draw the optical path length differences versus time epoch for the Unequal-arm Michelson (X, Y, Z) TDIs and their sum X+Y+Z in Fig. 5 and other first-generation TDI configurations in Fig. 6 for TAIJI of arm length 3 Gm.

**Fig. 5** The optical path length differences for Unequal-arm Michelson (X, Y, Z) TDIs (left) and their sum X+Y+Z (right) for TAIJI. There is a clear cancellation of optical path length differences by 2 orders of magnitudes in the sum.

3.2 Numerical results of the first-generation TDI for new LISA

For new LISA, the optical path length differences versus time epoch for the Unequal-arm Michelson (X, Y, Z) TDIs and their sum X+Y+Z have been shown in Fig. 7, and other first-generation TDI configurations have been shown in Fig. 8.
4 NUMERICAL SIMULATION OF THE SECOND-GENERATION TDI FOR TAIJI AND NEW LISA

In this section, we do the numerical simulation for the second-generation TDIs listed in subsection 1.2.2. We plot the optical path length differences versus time epoch of these second-generation TDIs for TAIJI in subsection 4.1 and for new LISA in subsection 4.2.
Fig. 8 The optical path length differences for Sagnac ($\alpha$, $\beta$, $\gamma$); Relay (U, V, W); Beacon (P, Q, R); Monitor (E, F, G) TDIs for new LISA.

From the last diagram in Fig. 9 and 11, we noticed that, the accuracy of the TDI calculation for the path difference should be better than 3 $\mu$m (10 fs).

4.1 Numerical results of the second-generation TDIs listed in subsection 1.2.2 for TAIJI

For TAIJI having 3 Gm arm length, we show the optical path length differences versus time epoch for $n = 1$ and $n = 2$ configuration TDIs in Fig. 9, and the Sagnac $\alpha_2$, $\beta_2$ and $\gamma_2$ TDI configurations in Fig. 10.

4.2 Numerical results of the second-generation TDIs listed in subsection 1.2.2 for new LISA

For new LISA with 2.5 Gm arm length, we show the optical path length differences versus time epoch for $n = 1$ and $n = 2$ configuration TDIs in Fig. 11, and the Sagnac $\alpha_2$, $\beta_2$ and $\gamma_2$ TDI configurations in Fig. 12.

5 DISCUSSION AND OUTLOOK

We have optimized a set of 6-year (2200-day) TAIJI and new LISA mission orbits numerically using ephemeris framework starting at March 22, 2028. The line-of-sight Doppler velocities satisfy the respective requirements. The maximum magnitude and rms magnitude together with the upper-limit requirement versus arm length are plotted in the left panel of Fig. 13. In Fig. 13, we also plot those of LISA-like interferometers of arm lengths 1 Gm ($e$LISA), 2 Gm, 4 Gm, 5 Gm (classical LISA) and 6 Gm from Wang & Ni (2017). The upper-limit follows a linear trend. We calculate optical path length differences of various first-generation and second-generation TDIs for these mission orbits and compile
Fig. 9  The difference of two optical path lengths vs. time epochs for \([ab, ba]\), \([cd, dc]\) and \([ef, ef]\) TDI configurations \((n = 1)\), and for all \(n = 2\) TDI configurations for TAIJI.

Fig. 10  The difference of two optical path lengths vs. time epochs for Sagnac-type \(\alpha 2\), \(\beta 2\), and \(\gamma 2\) TDIs for TAIJI.

them in Table 1 and Table 2 for easy comparison. We list the presently recommended requirement in the last row of the tables. From the tables and the figures in sections 3 and 4, we can have the following conclusions:

i) All the first-generation TDIs violate their respective requirements. For eLISA of arm length 1 Gm, the deviation for X, Y, and Z TDIs could be up to a factor of 3.6; for the new LISA case of 2.5 Gm arm length, a factor of 9.6; for TAIJI case of 3 Gm arm length, a factor of 12.5; for the classical LISA
Fig. 11  The difference of two optical path lengths vs. time epochs for $[ab, ba]$, $[cd, dc]$ and $[ef, ef]$ TDI configurations ($n = 1$), and for all $n = 2$ TDI configurations for new LISA.

Fig. 12  The difference of two optical path lengths vs. time epochs for Sagnac-type $\alpha^2$, $\beta^2$, and $\gamma^2$ TDIs for new LISA.

of 5 Gm, a factor of 22.3. If $X$, $Y$, and $Z$ TDIs are used for the GW analysis, either the TDI requirement needs to be relaxed by the same factor or laser frequency stability requirement needs to be strengthened by this factor. In the right panel of Fig. 13, we plot the largest value of the rms averages of $X$, $Y$ and $Z$ TDIs versus arm length. It looks like a power law dependence with power index of about 2.3 on the arm length.
Fig. 13 Left panel: Line-of-sight Doppler velocities (maximum and rms average in 2200 days) vs. arm length. Right panel: The largest of the rms averages of X, Y and Z TDIs vs. arm length.

(ii) From Table 1, all the first-generation TDIs do not satisfy their respective requirements. From Table 2, all the second-generation TDIs for eLISA and new LISA satisfy their respective requirements with good margins. For TAIJI, all the second-generation TDIs except the [a²b², b²a²] series which are marginal are well below their respective requirements for the laser frequency noise cancellation. For classical LISA, the [a²b², b²a²] and the [abab, baba] series TDIs do not satisfy the requirement while others do. Hence, to use the first-generation TDIs, the requirement must be relaxed with accompanying technology development. To use the second-generation TDIs, the corresponding GW response and sensitivity must be calculated and applied for the GW data analysis.

(iii) Experimental demonstration of TDI in laboratory for LISA has been implemented in 2010-2012 (de Vine et al. 2010; Mitryk et al. 2012). Therefore, the requirement of TDI for TAIJI, eLISA and ASTROD-GW which based on the LISA requirement is essentially demonstrated. Considering the current development progress of laser technology, the laser frequency noise requirement may be achieved to compensate for 1-2 order TDI relaxation in 10 years. For TAIJI and new LISA, the X, Y and Z TDIs could still be considered if this development would be realized and could be used for one-order more stringent mission requirement.

(iv) The optimistic observation start for TAIJI and new LISA could be in 2028. For other starting dates, similar orbits could be worked out.
