#### Abstract

We compile a blue AGN sample from SDSS and investigate how the ratio of hard X-ray to bolometric luminosity depends on the Eddington ratio and black hole mass. Our sample comprises 240 radio-quiet Seyfert 1 galaxies and QSOs. We find that the fraction of hard X-ray luminosity $\left(\log \left(L_{2-10 \mathrm{keV}} / L_{\text {bol }}\right)\right)$ decreases with an increase of the Eddington ratio. We also find that the fraction of hard X-ray luminosity is independent of the black hole mass for radio-quiet AGNs. The relation of $\log \left(L_{2-10 \mathrm{keV}} / L_{\mathrm{bol}}\right)$ decreasing with increasing Eddington ratio indicates that X-ray bolometric correction is not a constant, from a larger sample supporting the results of Vasudevan \& Fabian. We interpret our results by the disk corona evaporation/condensation model. In the frame work of this model, Compton cooling becomes efficient in cooling the corona at high accretion rates (in units of Eddington rate), leading to condensation of coronal gas to the disk. Consequently, the relative strength of the corona to the disk becomes weaker at higher Eddington ratios. Therefore, the fraction of hard X-ray emission to disk emission and hence to the bolometric emission is smaller at higher Eddington ratios. The independence of the fraction of hard X-ray luminosity with respect to the mass of the black hole can also be explained by the disk corona model since the coronal structure and luminosity (in units of Eddington luminosity) are independent of the mass of black holes.

Key words: accretion: accretion disks - galaxies: active - X-rays: galaxies

## 1 INTRODUCTION

Accretions onto supermassive black holes are the key processes that produce the spectral energy distribution in AGNs, including the Big Blue Bump, soft X-ray excess, $\mathrm{Fe} \mathrm{K} \alpha$ lines at 6.4 keV and the hard X-ray tail. These observed spectral properties indicate that the cold and hot gas coexist near the central supermassive black hole. According to commonly accepted theory, the optical/UV radiations are emitted from a geometrically thin and optically thick disk (i.e. the cold gas) (e.g., Shakura \& Sunyaev 1973; Lynden-Bell \& Pringle 1974), and the hard X-rays arise from hot optically thin and geometrically thick accretion flows, such as the disk corona (Haardt \& Maraschi 1991, 1993; Nakamura \& Osaki 1993; Svensson \& Zdziarski 1994; Kawaguchi et al. 2001; Cao 2009) or advection-dominated accretion flows (ADAF) (e. g., Narayan \& Yi 1994, 1995; Narayan et al. 1998).

The disk corona model was proposed to explain the observed X-ray emission in Cyg X-1 (Bisnovatyi-Kogan \& Blinnikov 1976; Liang \& Price 1977). The accretion in the corona is supplied with

[^0]material and energy through disk evaporation (e.g., Meyer \& Meyer-Hofmeister 1994; Liu et al. 1999) or a magnetic process (e.g. Galeev et al. 1979; Stella \& Rosner 1984; Liu et al. 2002a, 2003). In AGNs, a hot corona sandwiched by a disk is thought responsible for emitting the X-rays (e.g. Haardt \& Maraschi 1991; Nakamura \& Osaki 1993; Kawaguchi et al. 2001; Liu et al. 2002a, 2003). In the context of these studies, it is often assumed that a fraction $(f)$ of accretion energy is released in the corona from the results of fits of individual AGN spectra. Questions arise as, is the fraction $f$ dependent on the Eddington ratio and the black hole? How does the relative strength of the corona to the disk vary with the Eddington ratio and the black hole mass?

In this work, we attempt to investigate these issues by using observations. We compile a large blue AGN sample of 240 objects derived from Dong et al. 2008 (hereafter Dong08), in which the objects are selected from the Sloan Digital Sky Survey (SDSS) DR4 spectral data and they are less affected by dust extinction. We investigate the correlation between the coronal component and Eddington ratio. We show how the coronal luminosity fraction varies with the Eddington ratio and black hole mass for radio-quiet (RQ) AGNs. The results are compared with previous results of Wang et al. (2004) for a sample of 56 RQ AGNs observed by ASCA and Yang et al. (2007) for a combined sample from different observational satellites. Our aim is to study the physical relation between the disk and the corona.

The outline of the paper is the following. In Section 2, the black hole mass, and the optical and X-ray luminosities are calculated. In Section 3, the overall properties of the sample and the correlation analyses are presented. In Section 4, the statistical results are interpreted by the disk corona model. The discussion and conclusions are given in Sections 5 and 6, respectively.

## 2 THE SAMPLE AND DATA REDUCTION

Our sample is derived from a blue AGN sample in Dong08. These blue AGNs are selected from the Sloan Digital Sky Survey (SDSS) DR4 spectral data, including Seyfert 1 galaxies and QSOs. They are less affected by dust extinction. In order to investigate the relation between the disk and the corona, and whether and how the black hole mass and the Eddington ratio affect this relation, we select the objects by the following criteria:
(1) The objects are detected or covered by the Faint Images of Radio Sky at Twenty Centimeters (FIRST) survey;
(2) The X-ray flux is available;
(3) Combining the radio with the optical data, we can determine the radio loudness and the RQ AGNs are selected.

According to the above criteria, we analyze the sample in Dong08. Given the upper limit to the radio flux, 404 AGNs are detected or covered by FIRST. After matching the ROSAT bright and faint SRC Catalog database ( ROSAT-SRC) with a distance criterion between the optical and X-ray source of $\Delta \leq 60^{\prime \prime}$ (Voges et al. 1994), we obtain a sample containing 258 AGNs.

We use the radio-loudness definition (Ivezić et al. 2002) to divide RQ and radio-loud (RL) AGNs, that is,

$$
\begin{equation*}
R_{i} \equiv \log \left(\frac{F_{20 \mathrm{~cm}}}{F_{i}}\right)=0.4(i-t) \tag{1}
\end{equation*}
$$

where $F_{i}$ and $F_{20 \mathrm{~cm}}$ are flux densities at the $I$-band and 20 cm respectively, $i$ is the $I$-band magnitude, and $t=-2.5 \log \left(F_{20 \mathrm{~cm}} / 3631 \mathrm{Jy}\right)$. Objects with $R_{i}>1$ are RL and objects with $R_{i}<1$ are RQ. According to this definition, 240 ( $93 \%$ ) objects in the sample are RQ and 18 ( $7 \%$ ) objects are RL. We mainly analyze these 240 RQ objects in order to constrain the accretion mechanism.

The black hole mass, $M_{\mathrm{BH}}$, is a fundamental parameter of AGNs. Different methods have been developed to estimate the black hole mass (Woo \& Urry 2002 and references therein; Vestergaard \& Peterson 2006), of which the reverberation mapping is the most widely used method (Peterson 1993; Peterson et al. 2004). In the reverberation mapping method, the distance of the broad line region (BLR) from the central black hole can be deduced from the time lag between continuum and emission lines. By
combining the distance with the measured emission line width, the black hole mass can be determined. In our sample, we take the FWHM $(\mathrm{H} \beta)$ as the circular velocity in BLR. The size/distance of the BLR is given by an empirical relation with the continuum luminosity at $5100 \AA$ (Vestergaard \& Peterson 2006). Thus, the mass of black holes for RQ AGNs can be estimated as

$$
\begin{equation*}
\log M_{\mathrm{BH}}(\mathrm{H} \beta)=\log \left\{\left[\frac{\operatorname{FWHM}(\mathrm{H} \beta)}{1000 \mathrm{~km} \mathrm{~s}^{-1}}\right]^{2}\left[\frac{\lambda L_{\lambda}(5100 \AA)}{10^{44} \mathrm{erg} \mathrm{~s}^{-1}}\right]^{0.5}\right\}+(6.91 \pm 0.02) \tag{2}
\end{equation*}
$$

The bolometric luminosity of AGNs is approximately calculated from optical continuum luminosity, $L_{\mathrm{bol}} \approx 9 \lambda L_{\lambda}(5100 \AA)$ (Elvis et al. 1994). The Eddington ratio ( $L_{\mathrm{bol}} / L_{\mathrm{Edd}}$ ) is then calculated from the bolometric luminosity and black hole mass,

$$
\begin{equation*}
L_{\mathrm{bol}} / L_{\mathrm{Edd}}=0.072 \frac{\lambda L_{\lambda}(5100 \AA)}{10^{44} \mathrm{erg} \mathrm{~s}^{-1}}\left(\frac{M_{\mathrm{BH}}}{10^{8} M_{\odot}}\right)^{-1} \tag{3}
\end{equation*}
$$

where the Eddington luminosity is $L_{\mathrm{Edd}}=1.25 \times 10^{38} M_{\mathrm{BH}} / M_{\odot} \mathrm{erg} \mathrm{s}^{-1}$.
We get the X-ray flux densities from the count rates using the energy to counts conversion factor (ECF) for power-law spectra and Galactic absorption, where the power-law photon indices and the corresponding absorption column densities $\left(N_{\mathrm{H}}\right)$ are estimated from the two hardness ratios given by the ROSAT-SRC. With the integrated flux densities in $0.1-2.4 \mathrm{keV}$ and power-law indices $\Gamma$, we deduce the monochromatic flux at 2 keV . After deriving the flux at 2 keV , we extrapolate X -ray flux ( $F_{\text {int }}$ ) in the range from 2 keV to 10 keV by assuming a constant hard X -ray photon index, $\Gamma=1.9$ (Pounds et al. 1990; Reeves \& Turner 2000). The X-ray luminosity is then calculated by the standard luminosityflux relation,

$$
\begin{equation*}
L=4 \pi d_{\mathrm{L}}^{2} F_{\mathrm{int}}(1+z)^{-(1-\alpha)} \tag{4}
\end{equation*}
$$

where $\alpha=\Gamma-1$ and $d_{\mathrm{L}}$ is the luminosity distance related to the redshift and cosmology model.
Throughout this paper, we adopt the cosmology model with $H_{0}=70 \mathrm{~km} \mathrm{~s}^{-1} \mathrm{Mpc}^{-1}, \Omega_{\mathrm{M}}=0.3$, $\Omega_{\Lambda}=0.7$. Our sample is listed in Table 1.

## 3 DATA ANALYSIS AND RESULTS

### 3.1 Properties of the Sample

Figure 1 shows the histogram of black hole masses and Eddington ratios in our sample. It can be seen that the mass of black holes covers a large range from $10^{6}$ to $10^{10} M_{\odot}$. The center of the distribution of $M_{\mathrm{BH}}$ for the sources is greater than $10^{7} M_{\odot}$. The histogram of the Eddington ratios of the sample shows that the Eddington ratios range from $10^{-2.5}$ to 1.0 ; most of the objects show a high accretion rate. If the accretion mode in AGNs is similar to that in black hole X-ray binaries, the high accretion rates of our sample indicate that the thin disk extends down to the innermost stable circular orbit. Hence, the hard X-rays arise from a disk corona rather than an ADAF.

### 3.2 Correlation Analysis and Results

We plot the ratio of X-ray luminosity to the bolometric luminosity vs. the mass of black holes and vs. the Eddington ratio for RQ sources in Figure 2. In the upper two panels, the vertical axis is the logarithm of the fraction of hard X-ray luminosity to bolometric luminosity $\left(\log \left(L_{2-10 \mathrm{keV}} / L_{\mathrm{bol}}\right)\right.$ ), while in the lower panels, the vertical axis is logarithm of the fraction of soft X-ray luminosity $(0.1-2.4 \mathrm{keV})$ to the bolometric luminosity. Comparing the upper and lower panels, one can see that the distribution trends are different for the soft X-ray and hard X-ray fractions.

We test the correlations between $\log \left(L_{2-10 \mathrm{keV}} / L_{\mathrm{bol}}\right)$ and $\log \left(M_{\mathrm{BH}}\right)$ and between $\log \left(L_{2-10 \mathrm{keV}} /\right.$ $L_{\mathrm{bol}}$ ) and the Eddington ratio by the method of Spearman's rank correlation analysis (William et al. 1992). We calculate the Spearman's rank correlation coefficient ( $\rho$ ) and the two-sided significance of

Fig. 1 Left panel: the histogram of the black hole masses for our sample. We can see that the center of the distribution of $M_{\mathrm{BH}}$ of the RQ sources is nearly $10^{8.0} M_{\odot}$. Right panel: the histogram of the Eddington ratio for the sources. Most of the sources show high accretion rates.
its deviation from zero ( $P_{\text {Null }}$ ), representing the probability for randomness of the observed correlation of two variables. Significant correlation of two variables is accepted if $P_{\text {null }}$ is less than 0.05 . For our sample, the coefficient $\rho$ between $\log \left(L_{2-10 \mathrm{keV}} / L_{\mathrm{bol}}\right)$ and $\log M_{\mathrm{BH}}$ is 0.001 , and $P_{\text {Null }}$ is 0.988 . This means that the fraction of hard X-rays is independent of black hole mass. For the relation between the hard X-ray fraction and Eddington ratio, we get $\rho=-0.17$ and $P_{\text {Null }}=0.008$. This indicates that for RQ AGNs, the hard X-ray fraction correlates with the Eddington ratio, and with the increase of the

Fig. 2 Fraction of X-ray luminosity in the bolometric luminosity vs. the mass of the black hole and Eddington ratio for our sample. The top panels show how $\log \left(L_{2-10 \mathrm{keV}} / L_{\mathrm{bol}}\right)$ depends on $\log M_{\mathrm{BH}}$ and $\log \left(L_{\mathrm{bol}} / L_{\mathrm{Edd}}\right)$. The bottom panels describe the trend of $\log \left(L_{0.1-2.4 \mathrm{keV}} / L_{\mathrm{bol}}\right)$ varying with $\log M_{\mathrm{BH}}$ and $\log \left(L_{\mathrm{bol}} / L_{\mathrm{Edd}}\right)$. We can see that $\log \left(L_{0.1-2.4 \mathrm{keV}} / L_{\mathrm{bol}}\right)$ increases with decrease of the black hole mass and increase of the Eddington ratio.

Eddington ratio, the hard X-ray fraction decreases. This result is qualitatively consistent with the work of Wang et al. (2004).

In addition, we analyze the correlation of the soft X-ray fraction with the black hole mass and Eddington ratio. It is found that the soft X-ray fraction in the bolometric luminosity depends on black hole mass $\left(\rho=-0.26, P_{\text {Null }}=4.085 e-5\right)$, in contrast to the case of hard X-rays. The soft X-ray fraction also positively correlates with the Eddington ratio ( $\rho=0.18, P_{\text {Null }}=0.005$ ), contrary to the trend of the hard X-ray fraction.

## 4 INTERPRETATION OF THE CORRELATIONS WITH DISK CORONA MODEL

The hard X-ray radiation from RQ AGNs with a high Eddington ratio is commonly thought to be produced from a disk corona as a result of Comptonization of the softer photons arising from the accretion disk (e.g. Haardt \& Maraschi 1993; Kawaguchi et al. 2001; Liu et al. 2003; Cao 2009). If the bolometric luminosity is contributed dominantly by the disk $\left(L_{\mathrm{d}}\right)$ and corona $\left(L_{\mathrm{c}}\right)$, the fraction of hard X-ray luminosity in the total luminosity represents the strength of the corona relative to the disk. Thus, the negative correlation between the fraction of hard X-rays and the Eddington ratio for RQ AGNs indicates that the corona relative to the disk becomes weaker as the Eddington-scaled accretion rate increases.

Theoretical calculations of radiations from the disk corona (Haardt \& Maraschi 1991, 1993) show that the spectral shape does not change with accretion rate. In other words, the ratio $(f)$ of X-ray luminosity and bolometric luminosity is predicted to be independent of the accretion rate. To explain the observational correlation between $f$ and the Eddington accretion rate, Wang et al. (2004), Yang et al. (2007) and Cao (2009) consider magnetic fields and different shear stress tensors. Here we introduce the disk corona evaporation and/or condensation model (Liu et al. 2002b). We show that even without
magnetic fields, the correlation can be simply a consequence of efficient condensation of coronal gas to the disk in the case of high accretion rates.

Assuming that the energy of photons from the disk is amplified by a factor of $A \equiv \Delta \epsilon / \epsilon$ in the process of collisions with electrons when going through the corona, for non-relativistic thermal distributions of electrons, $A$ is a function of electron temperature $\left(T_{\mathrm{e}}\right)$ and optical depth ( $\tau_{\mathrm{es}}$ ) of the corona,

$$
\begin{equation*}
A=\frac{4 k T_{\mathrm{e}}}{m_{\mathrm{e}} c^{2}} \tau_{\mathrm{es}} \tag{5}
\end{equation*}
$$

The fraction of hard X-ray luminosity is expressed as,

$$
\begin{equation*}
\frac{L_{2-10 \mathrm{keV}}}{L_{\mathrm{bol}}}=\frac{A L_{\mathrm{d}}}{A L_{\mathrm{d}}+L_{\mathrm{d}}}=\frac{1}{1+\frac{1}{A}} \tag{6}
\end{equation*}
$$

In the case of high accretion rate, disk radiations are strong, which leads to efficient inverse Compton scattering in the corona. As a consequence of over-cooling, part of the coronal gas condenses into the disk, thereby the optical depth decreases and hence the amplification factor is low. The higher the accretion rate is, the lower the density of the corona is. Therefore, from Equation (6), one can see that the fraction of X-rays decreases at high accretion rates. Thus, the negative correlation between the fraction of hard X-ray luminosity and the Eddington ratio can be explained by the coronal condensation to the disk as a consequence of pressure and energy balance between the disk and corona.

Detailed calculations of condensation rate and luminosity have been carried out by Liu et al. (2007) and Taam et al. (2008). In this model, when the Compton scattering is the dominant cooling mechanism, the luminosities from the corona and disk are respectively as follows (Taam et al. 2008),

$$
\begin{align*}
L_{\mathrm{c}} & =\int_{3 R_{\mathrm{s}}}^{R_{\mathrm{out}}} 2 \pi R H \frac{4 k T_{\mathrm{e}}}{m_{\mathrm{e}} c^{2}} n_{\mathrm{e}} \sigma_{\mathrm{T}} 4 \sigma T_{\mathrm{eff}}^{4}(R) d R \\
& =4.11 \times 10^{38} \alpha^{-\frac{7}{5}} m \dot{m}_{\mathrm{c}}^{\frac{7}{5}} \dot{m}_{\mathrm{d}}^{5}  \tag{7}\\
L_{\mathrm{d}} & =\int_{3 R_{\mathrm{s}}}^{R_{\mathrm{out}}} \sigma T_{\mathrm{eff}}^{4}(R) 4 \pi R d R \\
& =\int_{3 R_{\mathrm{s}}}^{R_{\text {out }}} \frac{3 G M \dot{M}_{\mathrm{d}}}{r}\left[1-\left(\frac{3 R_{\mathrm{s}}}{R}\right)^{\frac{23}{10}}\left[1-\left(\frac{3}{r}\right)^{\frac{1}{2}}\right]^{\frac{3}{5}} d r\right. \\
& =9.38 \times 10^{38} m \dot{m}_{\mathrm{d}} \int_{3}^{r_{\text {out }}} \frac{1}{r^{2}}\left[1-\left(\frac{3}{r}\right)^{\frac{1}{2}}\right] d r \tag{8}
\end{align*}
$$

where $r=R / R_{\mathrm{s}}$ ( $R_{\mathrm{s}}$ represents the Schwarzschild radius), $m=M_{\mathrm{BH}} / M_{\odot}, \dot{m}_{\mathrm{c}}$ is the Eddingtonscaled accretion rate in the corona and $\dot{m}_{\mathrm{d}}$ the one in the disk. Note that for a truncated inner disk lying under a corona, $\dot{m}_{\mathrm{d}}$ comes only from the condensation of coronal gas; while in the case of a full disk coexisting with a corona for AGNs discussed here, the accretion rate in the disk is mainly from the outer region, $\dot{m}_{\mathrm{d}}=\dot{m}-\dot{m}_{\mathrm{c}}$. We then derive the ratio of coronal luminosity to disk luminosity,

$$
\begin{equation*}
L_{\mathrm{c}} / L_{\mathrm{d}} \propto \alpha^{-\frac{7}{5}} \dot{m}_{\mathrm{c}}^{\frac{7}{5}} \dot{m}_{\mathrm{d}}{ }^{-\frac{2}{5}}=\alpha^{-\frac{7}{5}} \dot{m}_{\mathrm{c}}^{\frac{7}{5}}\left(\dot{m}-\dot{m_{\mathrm{c}}}\right)^{-\frac{2}{5}} . \tag{9}
\end{equation*}
$$

In the disk corona evaporation and/or condensation model, the coronal accretion flow is supplied by disk evaporation in the region around $300 R_{\mathrm{s}}$. The coronal flow rate $\dot{m}_{\mathrm{c}}$ can be as high as a few percent of the Eddington value if the accretion rate exceeds a few percent of the Eddington value. However, the coronal flow can partially condense into the disk in the inner region as a result of Compton cooling, and the condensation rate is larger at a higher accretion rate. This means that the coronal flow ( $\dot{m}_{\mathrm{c}}$ ) is lower at a higher accretion rate. From Equation (9), one can see that the ratio of coronal luminosity to
disk luminosity decreases with increasing accretion rate $\dot{m}$. Noting that the accretion rate in units of Eddington value is equal to the Eddington ratio, the disk corona evaporation and condensation model predicts that the ratio of X-ray luminosity to disk luminosity decreases with increasing Eddington ratio, which can explain the correlation obtained from our RQ AGN sample.

If magnetic fields are also taken into account as an additional heating method (Liu et al. 2003; Cao 2009), the coronal accretion flow can be higher and the corona can be stronger than that without magnetic fields. However, the trend that condensation is stronger at higher accretion rates does not change with the magnetic fields. Therefore, the variation of relative strength of the disk and corona with accretion rates keeps the same trend. Thus, with inclusion of magnetic fields, the model will still work in interpreting the correlations.

Another important feature of the disk corona evaporation and condensation model is that the coronal structure and evaporation/condensation properties are independent of the mass of the black hole if scaled properly. In fact, the model can be applied in both X-ray binaries and AGNs. Equation (9) shows that the luminosity ratio from the corona and the disk indeed does not vary with the mass of the black hole. Therefore, the model can explain why for our sample the fraction of hard X-ray luminosity is independent of the mass of the black hole.

## 5 DISCUSSION

### 5.1 Implication to the Hard X-ray Bolometric Correction

The bolometric luminosity is either estimated from the measured luminosity at $5100 \AA$ or from hard X-ray luminosity with fixed correction factors. However, our data analysis shows that the hard X-ray fraction in the bolometric luminosity decreases with increasing Eddington ratio for RQ AGNs. This means that the bolometric correction factor from hard X-rays, $k_{2-10 \mathrm{keV}}=L_{\mathrm{bol}} / L_{2-10 \mathrm{keV}}$, should increase with an increasing Eddington ratio. This result is in good agreement with that of Vasudevan \& Fabian (2007), which is drawn from 54 AGNs with available SEDs. Note that in our study, we calculate the bolometric luminosity from $9 \lambda L_{\lambda}(5100 \AA)$. If the bolometric correction factor for $L_{5100 \AA}$ also tends to increase with Eddington ratio (see fig. 15 of Vasudevan \& Fabian 2007), the hard X-ray fraction in bolometric luminosity would be even smaller at higher Eddington ratios for our sample. Therefore, our statistical results support that the bolometric correction for hard X-rays increases with an increasing Eddington ratio.

### 5.2 The Constant Photon Index

In order to investigate the strength of the corona, i.e. to get the hard X-ray flux, we use the same photon indices for all objects in our sample to extrapolate the hard X-ray emission from 2 keV flux. From the above analysis, we get a smaller absolute coefficient value ( $\rho$ ) between the fraction of hard X-ray luminosity and the Eddington ratio. However, if we note that for some individual objects, the spectra become softer when a source is brighter (e.g., Lu \& Yu 1999; Bian 2005; Middleton et al. 2008; Saez et al. 2008) and this effect is taken into account, the hard X-ray luminosity fraction should change with the Eddington ratio more steeply than our results since here we assume the photon index is constant when calculating the hard X-ray luminosity.

### 5.3 The Origin of Soft X-rays in $0.1 \mathbf{- 2 . 4} \mathbf{k e V}$

Our study also indicates that for the same RQ AGNs, the fraction of soft X-ray luminosity in the ROSAT energy band $(0.1-2.4 \mathrm{keV})$ anticorrelates with the mass of the black hole, as shown in Figure 2. If the soft X-rays are also from the corona, the correlation should be similar to that for hard X-rays, that is, the fraction of soft X-rays is independent of the black hole mass. On the other hand, if the disk emits dominantly in soft X-rays, the fraction of soft X-rays to the total luminosity should also be independent of the mass of the black hole since both the total luminosity and disk luminosity are proportional to the
mass of the black hole. We note that the effective temperature of the disk decreases with the mass of the black hole (e.g., Thorne 1974; Bonning et al. 2007), $\sigma T_{\text {eff }}^{4}=\frac{3 G M \dot{M}}{8 \pi R^{3}}\left[1-\left(3 R_{\mathrm{s}} / R\right)^{1 / 2}\right]$, reaching a maximum at $R=(49 / 36)\left(3 R_{\mathrm{s}}\right)$ (see Liu et al. 2007),

$$
\begin{equation*}
T_{\text {eff }, \max }=1.3 \times 10^{5}\left(M_{\mathrm{BH}} / 10^{8} M_{\odot}\right)^{-1 / 4} \dot{m}^{1 / 4} \mathrm{~K} \tag{10}
\end{equation*}
$$

For an AGN with a high mass black hole, the disk does not emit in soft X-rays but rather in the opti$\mathrm{cal} / \mathrm{UV}$ band. With mass decrease, the high energy part of the disk spectrum could extend to soft X-rays. Consequently, the fraction of disk contribution to the soft X-ray component increases with the decrease of $M_{\mathrm{BH}}$. This could lead to a negative correlation between the fraction of soft X-rays and the mass of the black hole, qualitatively consistent with the observational results shown in Section 3. Therefore, the different correlations with black hole mass of the soft X-rays and hard X-rays may indicate that the soft X-rays are not only contributed from the corona but also the disk. Zhou et al. (1997) separated two components in the soft X-ray region through statistically analyzing the Big Blue Bump.

## 6 CONCLUSIONS

We compile a blue AGN sample containing Seyfert 1 galaxies and QSOs with 240 AGNs being RQ. We mainly investigate the dependence of the fraction of hard X-ray luminosity in bolometric luminosity $\left(\log \left(L_{2-10 \mathrm{keV}} / L_{\mathrm{bol}}\right)\right)$ on the black hole mass and Eddington ratio in RQ AGNs by using Spearman's rank correlation. We find that the fraction of hard X-ray luminosity in bolometric luminosity decreases with the increase of the Eddington ratio for RQ AGNs, while the fraction of hard X-ray luminosity in the bolometric luminosity is independent of the black hole mass for a wide range of black hole masses. The correlation between the hard X-ray and bolometric luminosity suggests that the hard X-ray bolometric correction increases at high Eddington ratios, confirming Vasudevan \& Fabian (2007)'s results from a larger sample. These observational features support the disk corona model developed by Meyer et al. (2000) and Liu et al. (2002b). Combining the theoretical model and the wide range of black hole masses in our sample, we suggest that the intrinsic accretion processes in AGNs and black hole X-ray binaries are similar.
