Abstract We use recent X-ray observations of the intracluster medium (ICM) of the galaxy group NGC 5813 to confront theoretical studies of ICM thermal evolution with the newly derived ICM properties. We argue that the ICM of the cooling flow in the galaxy group NGC 5813 is more likely to be heated by mixing of post-shock gas from jets residing in hot bubbles with the ICM, than by shocks or turbulent-heating. Shocks thermalize only a small fraction of their energy in the inner regions of the cooling flow; in order to adequately heat the inner part of the ICM, they would overheat the outer regions by a large factor, leading to its ejection from the group. Heating by mixing, which was found to be much more efficient than turbulent-heating and shocks-heating, hence, rescues the outer ICM of NGC 5813 from its predestined fate according to cooling flow feedback scenarios that are based on heating by shocks.

Key words: galaxies: active — galaxies: clusters: general — galaxies: groups: individual (NGC 5813) — galaxies: jets

1 INTRODUCTION

A negative feedback mechanism driven by active galactic nucleus (AGN) jets that inflate X-ray bubbles (X-ray deficient cavities) determines the thermal evolution of the intracluster medium (ICM) in the inner regions of cooling flow (CF) clusters and groups of galaxies (e.g., Pfrommer 2013; Perucho et al. 2014). In the feedback cycle the ICM feeds the AGN, and the AGN launches jets that heat the ICM.

A consensus is emerging that the feeding of the AGN is through cold clumps, in what is termed the cold feedback mechanism (Pizzolato & Soker 2005). Observations and theoretical studies in recent years have put the cold feedback mechanism on very solid ground (e.g., Revaz et al. 2008; Pope 2009; Pizzolato & Soker 2010; Edge et al. 2010; Wilman et al. 2011; Nesvadba et al. 2011; Cavagnolo et al. 2011; Gaspari et al. 2012a,b; McCourt et al. 2012; Sharma et al. 2012; Farage et al. 2012; Wagh et al. 2014; Banerjee & Sharma 2014; McNamara et al. 2014; Voit & Donahue 2015; Voit et al. 2015; Li et al. 2015; Prasad et al. 2015; Russell et al. 2015; Tremblay et al. 2015; Fogarty et al. 2015). The processes by which jets heat the ICM, on the other hand, are still in dispute. Based on observations of the galaxy group NGC 5813, Randall et al. (2011) and Randall et al. (2015) argue that shocks heat the ICM, hereafter referred to as the shocks-heating process. This was questioned by Soker et al. (2013), and is further studied in the present paper. Based on deep X-ray observations of the Perseus and Virgo cooling flow clusters, Zhuravleva et al. (2014) argue that the main heating process is via dissipation of ICM turbulence, hereafter called the turbulent-heating process. The third heating process is the mixing of cooling ICM with hot shocked gas from jets that resides in the hot bubbles, hereafter called the mixing-heating process. Gilkis & Soker (2012) and Hillel & Soker (2014) conducted numerical simulations and showed that the mixing-heating process is much more efficient than the shocks-heating process. In a recent paper, Hillel & Soker (2016) showed that the mixing-heating is also more efficient than the turbulent-heating when turbulence is driven by AGN activity. The turbulence, as observed in some clusters (e.g., Zhuravleva et al. 2015; Anderson & Sunyaev 2015), is a consequence of the same vortices that cause mixing.

To reach the conclusion that mixing-heating is the dominant process, it is mandatory to inflate bubbles by jets in a self-consistent manner. For example, the vortices that are induced inside and outside the bubbles must be taken into account as they play major roles in the formation of bubbles, their evolution and their interaction with the ICM (e.g. Omma et al. 2004; Heinz & Churazov 2005; Roediger et al. 2007; Sternberg & Soker 2008b; Gilkis & Soker 2012; Wagh et al. 2013). To inflate bubbles that resemble observed bubbles, our group has employed either slow (sub-relativistic) massive wide (SMW) jets (bipolar out-
flows), e.g., Sternberg et al. (2007), or precessing jets, e.g.,
Sternberg & Soker (2008a); see also Falcke-Gonçalves et al. (2010). SMW jets are supported by observations (e.g.,
Moe et al. 2009; Dunn et al. 2010; Arav et al. 2013). Both types of inflated bubbles will be described in the present
study.

In a recent paper, Randall et al. (2015) presented new observations of NGC 5813. Such detailed observations serve as a unique opportunity for us to confront our find-
ings, regarding heating the ICM with jet-inflated bubbles, against observations. We here confront the new observa-
tions with two types of previously conducted numerical simulations. In Section 3 we present a new study of the im-
plications on the heating process of large scale flows that are induced by the jet-inflated bubbles. In Section 4 we show that a careful treatment is required when studying the shocks that are induced by jet-inflated bubbles. To the best of our knowledge, this is the first study that has pointed to the influence of sound waves on the derived shock prop-
erties. But in Section 2, we first present a new analysis of the effect of many repeated shocks on the outskirts of the ICM in NGC 5813. In Section 5 we summarize our find-
ings, and conclude that although shocks play some role, mixing-heating is likely to play a much more significant role in the heating process.

2 IMPLICATIONS FOR THE OUTER ICM

The inefficiency of the shocks-heating process was discussed in Soker et al. (2013). To excite a shock with a Mach number of $M_a$, at radius $r$, the energy supplied by the AGN directly to the ICM, using the spherically symmetric Sedov solution for the shock, should be

$$E_{\text{shock}} \approx \left(\frac{M_a}{1.1}\right)^2 E_{\text{th}}(r),$$

where $E_{\text{th}}(r)$ is the thermal energy of the ICM inside radius $r$. According to Randall et al. (2015), to heat the cooling flow region of NGC 5813 inside $30 \text{kpc}$, about 140 shocks with a Mach number of $M_a \approx 1.2$ are required during one cooling time. By Equation (1), to reach this Mach number each shock is excited with an energy of

$$E_{\text{shock}} \approx (1.2/1.1)^2 E_{\text{in}} = 1.2 E_{\text{in}},$$

where we define $E_{\text{in}} \equiv E_{\text{th}}(r < 30 \text{kpc})$. Each shock supplies an energy of $E_{\text{in}}/140 = 0.01 E_{\text{in}}$. Removing this dissipated energy in the inner region (up to $30 \text{kpc}$), the energy that flows to the outer ICM regions within one cooling time at $r = 30 \text{kpc}$ is $E_{\text{out}} \approx 140(1.2 - 0.01) E_{\text{in}} \approx 160 E_{\text{in}}$. The ICM mass residing out at $r > 30 \text{kpc}$ can be crudely estimated from the new density profile given by Randall et al. (2015). The electron density profile from $r = 22 \text{kpc}$ to $r = 35 \text{kpc}$, the largest radius in their profile, can be fitted with

$$n_e(r) = 2.4 \times 10^{-3} \left(\frac{r}{30 \text{kpc}}\right)^{-2.8} \text{cm}^{-3}.$$  

Extrapolating this fit to large distances of hundreds of $\text{kpc}$, we can estimate the mass in the outer region to be $M_{\text{out}} \approx 10^{11} M_\odot \approx 2 M_{\text{in}}$. Based on ROSAT observations of poor groups of galaxies, Mulchaey et al. (1996) find the diffuse X-ray gas in a typical poor group extends up to $\sim 300 \text{kpc}$, and has a shallower density profile. If we take a shallower density profile of

$$n_{e-}(r) = 2.4 \times 10^{-3} \left(\frac{r}{30 \text{kpc}}\right)^{-1.5} \text{cm}^{-3},$$

(like in Eq. (5) below), the gas mass in the outer region to a distance of $300 \text{kpc}$ is $M_{\text{out}} \approx 5 \times 10^{11} M_\odot \approx 10 M_{\text{in}}$.

Randall et al. (2015) do mention that the energy carried by the bubble is transferred out by the buoyant bub-
bles. However, the shocks turn into sound waves that dissi-
plate their energy after a long time in the ICM. By the simple estimate made above, the temperature of the outer gas should be

$$T_{\text{out}} \approx 10 \left(\frac{T_{\text{in}}}{0.7 \text{keV}}\right) \left(\frac{E_{\text{out}}}{150 E_{\text{in}}}/\frac{M_{\text{out}}}{10 M_{\text{in}}}\right)^{-1} \text{keV.}$$

(4)

This is a temperature larger than the virial temperature of the group.

It seems that for the shocks-heating process to be effective in the inner region, the outer ICM would escape in a time much shorter than the cooling time, hence destroy-
ing observed structure of the ICM. Clearly, a much more efficient heating mechanism than shocks is required to rescue the ICM of NGC 5813. Mixing-heating is this process (Hillel & Soker 2014, 2016).

3 LARGE SCALE FLOW

In the shocks-heating scenario presented by Randall et al. (2011) and Randall et al. (2015), tens of jet-launching episodes along the same axis heat the ICM. They do not consider any flow that might develop in the ICM. Here we show that a large-scale meridional flow develops as a result of multi-jet activity cycles. For that we present the results from three-dimensional (3D) numerical simulations we have carried out recently (Hillel & Soker 2016). We briefly present the main characteristics of the numerical set up here; more details can be found in that paper.

We use the PLUTO code (Mignone et al. 2007) for the hydrodynamic simulations in a 3D Cartesian grid with adaptive mesh refinement. The computational grid is in the octant where the three coordinates $x, y$ and $z$ are positive. At the $x = 0, y = 0$ and $z = 0$ planes we apply reflective boundary conditions. The $z$ coordinate is chosen along the initial axis of the jets. The computational grid spans the cube $0 \leq x, y, z \leq 50 \text{kpc}$.

At the boundary $z = 0$, we inject a jet into the grid with a half-opening angle of $\theta_j = 70^\circ$ (Sternberg et al. 2007). The jet is injected during each active episode lasting $10 \text{Myr}$, and when the jet is turned off for $10 \text{Myr}$, reflective boundary conditions apply in the whole $z = 0$ plane. The initial jet velocity is $v_j = 8200 \text{km s}^{-1}$ corresponding to a Mach number of about $10$ relative to the ICM.
The power of the two jets together (we simulate only one jet) is $E_{3j} = 2 \times 10^{45}$ erg s$^{-1}$ (half of the power is dissipated in each direction), and the mass deposition rate is $M_{3j} = 94 M_{\odot}$ yr$^{-1}$.

The simulations presented here assume that jets start with wide opening angles. As stated in Section 1, there are observations of SMW outflows from AGNs. As well, the effect of rapidly precessing jets in inflating bubbles is very similar to that of wide jets (Sternberg & Soker 2008a), but it is simpler to simulate wide jets (for precessing jets see the next section). The main issue is to inflate bubbles, a process that involves the formation of vortices. Although magnetic fields are present in jets, as inferred from the radio emission, we assume here that they do not play a dynamical role. As we heat by mixing, we attribute no role to heat conduction on large scales (only on very small scales does mixing bring the ICM and the hot bubble gas very close to each other).

The simulation begins with an isothermal box of gas at an initial temperature of $T_{\text{ICM}}(0) = 3 \times 10^7$ K with a density profile of (e.g., Vernaleo & Reynolds 2006)

$$\rho_{\text{ICM}}(r) = \frac{\rho_0}{1 + (r/a)^2}^{3/2},$$

with $a = 100$ kpc and $\rho_0 = 10^{-25}$ g cm$^{-3}$. A gravity field is added to maintain an initial hydrostatic equilibrium, and is kept constant in time. We include radiative cooling in the simulations, where the tabulated cooling function is taken from Table 6 in Sutherland & Dopita (1993).

To reveal the large scale flow, we follow an artificial flow quantity called a ‘tracer.’ The tracer is frozen-in to the flow, and hence indicates how the spreading behaves with time for gas starting in a certain volume. A tracer’s initial value is set to $\xi(0) = 1$ in a certain volume and $\xi(0) = 0$ elsewhere. As the traced gas mixes with the ICM or material from the jet, its value drops to $0 < \xi(t) < 1$. We choose to trace the gas starting inside a torus around the $z$ axis. The radius of the cross section of the torus is 2.5 kpc, and it is centered at $(y, z) = (20, 15)$ kpc, or more generally $(\sqrt{x^2 + y^2}, z) = (20, 15)$ kpc.

In Figure 1 we present the evolution of the tracer at six times in the meridional plane $(y, z)$. Note that the axis of the jet is along the $z$ axis, which is the horizontal axis in the figure. The evolution of other quantities in the $(x, z)$ meridional plane is presented by Hillel & Soker (2016). In the panels shown in the left column, the arrows represent flow velocity, with length linear with velocity up to an upper limit of $v_m = 400$ km s$^{-1}$. Faster regions are presented with an arrow length corresponding to $v_m$. In the panels shown in the right column, the arrows represent mass flux $\phi = v_p$.

There are several prominent properties of the flow that are relevant to the present study and are revealed in Figure 1.

1. Mixing. The vortices created during the inflation of the bubble mix hot bubble gas with the ICM gas. This can be clearly seen by following the evolution of the tracer. This is the main heating mechanism of the ICM by jets (Gilkis & Soker 2012; Hillel & Soker 2014, 2016).

2. Outward then inward motion. The shocks running through the ICM followed by sound waves behind them can push gas out. The traced gas presented here is pushed from a torus cross section centered at $(y, z) = (20, 15)$ kpc to an elongated shape centered at $(y, z) \simeq (29, 15)$ kpc at $t \simeq 100$ Myr. However, then it turns around and flows inward. It is heated only when it starts to be mixed with the hot bubble gas at $t \simeq 110$ Myr (Hillel & Soker 2016).

3. Large scale meridional flow. At late times of $t \gtrsim 200$ Myr, and after about 10 jet-activity episodes (cycles), a large-scale inflow takes place near the equatorial plane. This results from the dragging of ICM gas by the outflowing jets along their axis, here the horizontal $z$-axis. It seems though that in reality the axis of the jets will change their direction and no such large meridional flow will develop. This change in direction can be seen in the three bubble-pairs in NGC 5813 (Randall et al. 2015).

It should be noted that the simulations presented here are general, and have parameters that fit clusters of galaxies, but do not fit groups of galaxies, such as NGC 5813. For example, the power of jets here is 200-1000 times the power inferred for the bubble formation in NGC 5813 (Randall et al. 2015). The consequence is that the mixing region extends far beyond a radius of 30 kpc. For a much lower power of the jets as appropriate for NGC 5813, we would get a much smaller mixing region, one that fits the cooling flow region of NGC 5813.

The main conclusion of this section is that one cannot assume that the activity shown by jets repeats itself along the same direction for many episodes, but the ICM in the equatorial plane (the plane perpendicular to the axis of the jets) does not flow inward. The flow inward will mix ICM gas with bubble gas, leading to heating by mixing that is much more efficient than the shocks-heating process.

4 POST-SHOCK FLOW

Randall et al. (2015) find the observed rise in temperature across the shocks to be less than what is expected based on the Mach numbers they derive from their calculated density jumps across the shocks. They attribute the discrepancy to the inability of the deprojected temperature measurements to resolve the temperature jump due to the narrow width of the shock and the rarefied cool gas behind the shock (Randall et al. 2011).

We raise another possibility here. When a bubble is inflated by a jet, sound waves are excited and trail the shock wave (Sternberg & Soker 2009). The sound waves can compress gas behind the shock, and raise the density behind the shock much more than they raise the tempera-
Evolution with time of a traced gas simulated by Hillel & Soker (2016). At \( t = 0 \) the traced gas was contained in a torus whose axis is the \( z \)-axis and whose cross section is a circle centered at \((\sqrt{x^2 + y^2}, z) = (20, 15) \) kpc with a radius of \( r = 2.5 \) kpc. Color coding represents the tracer value \( \xi \). The axis of the jets is along the horizontal \( z \)-axis in the panels. In the three panels on the top the arrow lengths are linear with velocity, up to a maximum value of \( v_m = 400 \) km s\(^{-1}\). Faster regions have an arrow length corresponding to \( v_m \). The arrows in the bottom panels show the mass flux \( \phi = v \rho \). A length of 1 kpc on the map corresponds to \( \phi = 2.3 \times 10^{-23} \) km s\(^{-1}\) g cm\(^{-3}\).

In Figures 2 and 3 we present results from Sternberg & Soker (2009), where all technical details are given.

The relevant properties of these simulations are as follows. The simulations are performed in half of the meridional plane using the two-dimensional version of the VH1 code (Blondin et al. 1990; Stevens et al. 1992) in spherical coordinates with a resolution of \( 256 \times 256 \). Gravity was included in these simulations. Two opposite jets are launched along the \( x \)-axis.

In the case of wide jets, two opposite jets were injected in the time period from \( t = -10 \) Myr until \( t = 0 \), each jet with a half opening angle of \( \alpha = 70^\circ \). Their combined mass outflow rate was \( \dot{M}_{2j} = 10 M_\odot \) yr\(^{-1}\) and the initial velocity was radial with \( v_j = 7750 \) km s\(^{-1}\). The total power of the two jets was \( \dot{E}_{2j} = 2 \times 10^{44} \) erg s\(^{-1}\). This case is presented in Figure 2.

In the case of the precessing jets the two opposite jets have the same mass outflow rate and velocity as in the case of wide jets, but they were injected at any given time with a half opening angle of \( \alpha = 5^\circ \). In the axisymmetric grid employed, the jets are actually precessing very rapidly around the symmetry axis (i.e., forming a pattern of 3D tori). The angle \( \theta \) between the symmetry axis and the axis of the jets was varied in a random way. The precession period, i.e., the time the jet returns to the same angle \( \theta \), is \( T_{\text{prec}} = 0.1 \) Myr. The interaction of the jet with the ICM is similar to that of a wide jet with a half opening angle of \( \alpha \approx 50^\circ \). The jets were active between \( t = -18 \) Myr and \( t = 0 \). This case is presented in Figure 3.

We argue that Randall et al. (2015) somewhat overestimate the Mach numbers in the shocks that they study in NGC 5813.

5 SUMMARY

We reexamined the claim made by Randall et al. (2011) and Randall et al. (2015) that the ICM in the cooling flow group of galaxies NGC 5813 is heated by many shock waves excited by repeated jet-launching episodes. It was already argued by Soker et al. (2013) that the shocks-heating mechanism is inefficient, and cannot account for the ICM properties of NGC 5813. Here however, we performed three new analyses and confronted theoretical studies with the newly derived properties of the ICM of NGC 5813. (i) We presented a new analytical analysis of the effect of many shocks on the outskirts of the ICM in NGC 5813. (ii) We discussed the role of
ICM in such a case as static. Such a flow leads to a very vigorous mixing of the ICM with hot gas inside the bubbles. Heating by mixing becomes the dominate heating mechanism even for gas perpendicular to the axis of the jets (Gilkis & Soker 2012; Hillel & Soker 2014, 2016). We expect that in reality the axis of the jets will change over time, and the meridional flow will not be as prominent as found here.

In Section 4 we showed that sound waves propagating behind a shock wave can form a region behind the shock where the density increases above the post-shock value, but the temperature does not. This might explain the finding of Randall et al. (2015) that the temperature jumps across the shocks in NGC 5813 are lower than those expected for the Mach numbers they deduced based on the density jumps. If true, it implies that Randall et al. (2015) overestimated the Mach numbers in the three shocks they found in NGC 5813.

Our main conclusion is that shocks cannot be the main heating process of the ICM in NGC 5813. Heating by mixing seems to be the main heating process of the ICM by jets (Gilkis & Soker 2012; Hillel & Soker 2014, 2016). The mixing is caused by vortices that are formed during inflation of the bubbles. To reveal the properties of the vortices in numerical simulations, it is crucial to inflate bubbles in a...
self-consistent manner. When that is done, it is found that the mixing also operates perpendicularly to the axis of the jets.

The vortices lead to turbulence in the ICM. Therefore, the finding of moderate turbulence in the inner region of NGC 5813 by Werner et al. (2009) and de Plaa et al. (2012), as well as in other clusters (Zhuravleva et al. 2014, 2015; Anderson & Sunyaev 2015), strengthens the argument that the mixing-heating process is the dominant heating process. Some heating by the dissipation of turbulence takes place as well, but it accounts for at most ≈ 20% of the total heating (Hillel & Soker 2016).
