Received 2017 November 25; accepted 2018 January 25

Abstract Using 172 plates taken with the 40-cm astrograph of the Sternberg Astronomical Institute (Lomonosov Moscow University) in 1976–1994 and digitized with a resolution of 2400 dpi, we discovered and studied 275 new variable stars. We present the list of our new variables with all necessary information concerning their brightness variations. As in our earlier studies, the new discoveries show a rather large number of high-amplitude Delta Scuti variables, predicting that many stars of this type remain not detected in the whole sky. We also performed automated classification of the newly discovered variable stars based on the Random Forest algorithm. The results of the automated classification were compared to traditional classification and showed that automated classification was possible even with noisy photographic data. However, further improvement of automated techniques is needed, which is especially important when considering the very large numbers of new discoveries expected from all-sky surveys.

Key words: techniques: photometric

# **1 INTRODUCTION**

The 20th century (more accurately, the time interval between the 1880s and 1990s) was the era of astronomical photography on plates and films. The number of analog photographs at observatories around the world is estimated to be about two million. Information on the existing plate stacks is collected in the Wide-field Plate Database (*www.wfpdb.org*), founded by M.K. Tsvetkov (Bulgaria).

Digitizing plate archives permits users, at the observatories where the archives are stored and elsewhere, to use the vast amount of information when applying modern digital reduction techniques for scientific studies that are important for modern astronomy. It also provides safety against events capable of destroying the analog photographs: fires, floods, etc., like the water main break that occurred at Harvard Observatory on 2016 January 16. Harvard plate stacks, the world-largest collection where about 500 000 sky photographs are kept, fortunately survived the terrible accident due to an effective response from emergency teams, but it is impossible to predict what accident will happen next and where. The process of digitizing Harvard stacks started long before the accident and is under way quite successfully (e.g., Grindlay et al. 2009; *http://dasch.rc.fas.harvard.edu/index.php*). At Moscow Observatory (now the Sternberg Astronomical Institute of Lomonosov Moscow University, SAI), direct photographs of the starry sky were taken regularly in 1895–1995 using different telescopes, with diameters of their objectives from 10 to 70 cm and focal lengths from 64 to 1050 cm, installed at SAI sites in Moscow, Crimea and elsewhere. The founder of the Moscow plate stacks was Prof. S.N. Blazhko (1870–1956). Details about this plate collection can be found in Shugarov et al. (1999). The total number of sky photographs (direct images) in the Moscow stacks is estimated as 60 000, and they were used in different SAI departments for different purposes.

The most important part of the Moscow plate stacks is 22 300 plates taken with the 40-cm astrograph (f = $160 \,\mathrm{cm}, 10^\circ \times 10^\circ$  field of view). This wide-field multilens astrograph was initially ordered by C. Hoffmeister (1892–1968) for the Sonneberg Observatory (Germany). In 1938–1945, 1658 sky photographs were obtained with the astrograph. In 1945, it was selected as a part of war reparations by B.V. Kukarkin (1909-1977), at that time an officer in the Soviet Army, later one of the founders of the General Catalogue of Variable Stars. In July, 1948 – April, 1951, the telescope was in operation at Simeiz Observatory, Crimea; in June, 1951 -February, 1958, at Kuchino Observatory near Moscow; in May, 1958, it became the first instrument in operation at the newly established Crimean station of the SAI in Nauchny settlement, Crimea (near the new territory of the Crimean Astrophysical Observatory). At this site, more than 20 800 plates were taken. The limiting magnitude in the central parts of the field, for our typical 45minute exposure time, is 17 - 18 magB. Unfortunately, distortions in the plate corners are large, deteriorating the limiting magnitude.

The main purpose of star photographs taken with the 40-cm astrograph was studies of variable stars. The program of observations with the astrograph included many fields. Rich fields contain about 300–500 sky photographs. In cases of overlapping fields, a star can sometimes be found on 700 plates or even more.

We describe our work on digitizing the Moscow plate collection in Section 2. Section 3 presents our new variable-star discoveries. Section 4 deals with statistics related to high-amplitude Delta Scuti (HADS) variable stars in our sample. In Section 5, we discuss an attempt at automated classification of the new variable stars found in this field. Our conclusions are summarized in Section 6. Samus & Li (2018) noted that our attempt at automated classification seemed to be sufficiently successful. We agree with their opinion.

## 2 DIGITIZING MOSCOW PLATES

Scanning of the plates in the Moscow collection was started in 2006 using two CREO EverSmart Supreme scanners, with resolution of about 2500 dpi. Unfortunately, electronic components in these scanners malfunctioned several years later and could not be repaired. In 2013, following advice from M.K. Tsvetkov, we purchased an Epson Expression 11000XL scanner and continued digitizing our collection using a resolution of 2400 dpi. Due to requirements for funding in Russian science, we decided to arrange the work so that scientific results would not be delayed till the scanning of the whole collection was completed. After finishing digitizing a field, we search for variable stars using the scans and study the discovered variables.

When searching for variable stars, determining their periods and plotting light curves, we commonly use the VaST software package developed by Sokolovsky & Lebedev (2018). VaST relies on SExtractor (Bertin & Arnouts 1996) for detecting sources, and measuring their positions (in pixel coordinates) and brightness.

We apply the following procedure to extract light curves from a series of digitized photographic images for a given sky region.

The grayscale TIFF images produced by the scanner are converted to FITS format using a custommade code (*ftp://scan.sai.msu.ru/pub/software/tiff2fits/*) and the mid-exposure Julian date (extracted from telescope logbooks) is recorded in the FITS header.

Pixel coordinates of a bright star visible in all images are used as the reference point to cut each image into overlapping  $1.2^{\circ} \times 1.2^{\circ}$  subfields. The subfields are positioned relative to the reference star and cover the same sky area even for plates that have a large offset from the nominal center of the field. We neglect the plate rotation at this stage, as it is known not to exceed  $3^{\circ}$  for any of the plates digitized so far.

Then, SExtractor (Bertin & Arnouts 1996) is applied to each subfield image to perform source extraction and circular aperture photometry. The VaST code (Sokolovsky & Lebedev 2018) performs cross-matching of the source lists (as the subfield images are not aligned perfectly) and constructs light curves in an instrumental magnitude scale. As the photographic density is a non-linear function of the number of incoming photons, we use the relation suggested by Bacher et al. (2005) to convert the measured instrumental magnitudes to the absolute scale set by the B magnitudes of USNO-B1.0 (Monet et al. 2003) stars within each subfield.

Astrometry.net (Lang et al. 2010; Hogg et al. 2008) is used to derive a blind plate solution for each subfield, which is needed to extract equatorial coordinates of the detected objects.

New variables discovered in the course of our project are given provisional variable-star names in the specially introduced Moscow Digital Variable (MDV) series. Test experiments that scanned small parts of plates resulted in discovering MDV 1-MDV 38. The list of these stars can be found in Kolesnikova et al. (2010). The first  $10^{\circ} \times 10^{\circ}$  field of the 40-cm astrograph, which was completely scanned and searched for variable stars by us, was that centered at the star 66 Oph  $(18^{h}00.3^{m}, +04^{\circ}22', J2000.0)$ . In this field, we discovered and studied 480 new variable stars, MDV 39-MDV 518 (Kolesnikova et al. 2008, 2010). The 77 new variable stars discovered in the field of SA9 (the center at 03<sup>h</sup>11.5<sup>m</sup>, +60°38', J2000.0; MDV 519–MDV 595) are discussed in Sokolovsky et al. (2014). In the present paper, we present our new results obtained in the field centered at the star 104 Her  $(18^{h}11.9^{m}, +31^{\circ}24', J2000.0)$ . We have discovered and studied 275 new variable stars.

# **3 NEW VARIABLE STARS**

The plate stacks of the SAI contain 172 plates centered at the star 104 Her ( $l = 58^{\circ}, b = 22^{\circ}$ ; 1976 March 31 - 1994 October 8). This is a moderately high-latitude field, and the star density is not very high. The plates were scanned with the Epson Expression 11000XL scanner, with resolution 2400 dpi, and searched for new variable stars using the VaST software. Identified variable stars were checked in the GCVS and VSX databases for being new. If photographic data, which have comparatively low photometric accuracy, left doubt as to whether a particular star was variable or not, we checked questionable cases using additional sources of photometric information: the ROTSE/NSVS database (Woźniak et al. 2004b), Catalina database (Drake et al. 2009) and ASAS-SN database (Kochanek et al. 2017). Six stars in the final list were confirmed on the basis of specially arranged CCD observations using telescopes of the SAI Crimean laboratory.

Figure 1 illustrates our technique of photographic photometry and search for variable stars. The VaST code checks all stars deviating along the ordinate from the most densely populated cloud for periodicity; additionally, non-periodic, strongly deviating stars (that can be non-period varies) are inspected by eye. Some of the outliers, those not marked with numbers, are mainly blended stars.

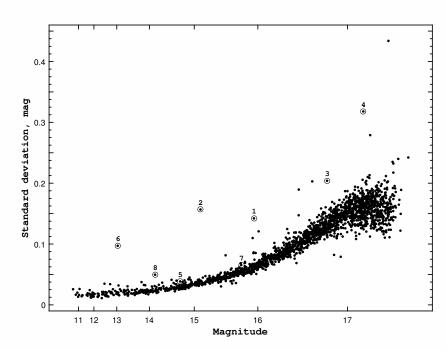

Our final list of newly discovered variable stars is presented in Table 1. It contains 275 new variables (MDV 596–MDV 870).

The columns of Table 1 present: the MDV number of the variable; its equatorial coordinates (J2000.0); its variability type; its period (for period varies); its variability range (photographic *B* magnitudes at maximum and minimum light, also values for the secondary minimum for eclipsing stars); numbers corresponding to remarks listed at the bottom of the table. The light curves of the variables can be found at our web site (*http://www.sai.msu.su/gcvs/digit/digit.html*).

We performed classification of all the new discoveries using the traditional approach employed by the General Catalogue of Variable Stars team that some of the authors belong to. This classification is principally based on the light curve shape but also takes into account all available additional information (period, amplitude, color index, etc.). Judging from our preferred classifications (the third column of Table 1), more than half of all discoveries (150 stars) are eclipsing variables. Among pulsating variables in Table 1, we often meet RR Lyrae variable stars (70 objects), and semiregular (SR) or irregular (LB, L) stars. There are also eight HADS variables, three Cepheids of the second type (CW), and a variable of the RV Tauri (RVA) type. Two variables are probable rotating spotted stars (type BY:). Figure 2 displays sample photographic light curves for several types of variables. We present our CCD light curves for two stars in Figure 3.

It is very interesting that our photographic search for new variable stars made it possible to also detect lowamplitude variable stars. The lowest peak-to-peak amplitude, 0.1 mag, was found for the EW eclipsing star MDV 640, quite reliably confirmed with data from the ASAS-SN survey.

We will address the period distribution of newly discovered eclipsing variable stars elsewhere. Here we only mention that, for EW stars, this distribution is evidently shifted towards shorter periods, as already noted

**Fig.1** A diagram illustrating the process of our search for variable stars. The *circled stars* are new or previously known variable stars. 1: NSVS J1812081+302718 (Woźniak et al. 2004a); 2: V1335 Her; 3: MDV 684; 4: MDV 700; 5: MDV 701; 6: MDV 705; 7: MDV 710; 8: MDV 713.

by Kolesnikova et al. (2010) for our discoveries in the field of 66 Oph.

#### **4 STATISTICS ON HADS VARIABLES**

Among short-period pulsating variable stars, a large fraction are Delta Scuti variables, mainly located in the region where the Cepheid instability strip intersects the main sequence. Most of them have small pulsation amplitudes; however, Delta Scuti stars exist with V-band or photographic amplitudes of 0.2 mag or higher. In most studies, such stars are called HADS variables. This is not a homogeneous variability type but a mixture of younger (Population I) stars and SX Phoenicis variables that belong to old galactic populations. A clear distinction between these variability types has not yet been achieved (see Balona 2016). In the following, we call all largeamplitude, short-period pulsating variable stars HADS variables. Our data do not permit a study of their multiperiodic behavior, which is quite typical for some of them.

From scans of the field centered at 66 Oph, we found 11 HADS stars with peak-to-peak amplitudes of 0.2 mag or higher. Kolesnikova et al. (2010) remarked that this result lead to the expected number of HADS variables missing from existing variable-star catalogs to be quite large, with the area of the studied field being only 0.24% of the whole area of the sky. The amplitudes of the new HADS variables are not small; they can be easily discovered using photographic plate collections and traditional techniques (eye estimates or measurements with microphotometers).

Expectations for many new HADS variables were not quite fulfilled in the field SA9 (Sokolovsky et al. 2014), where we discovered only one HADS variable.

In the present study, we found eight new HADS variable stars (two of them uncertain); there are also doubts

if MDV 790 is an EW or an HADS star, making the total number of new HADS stars nine (three of them are uncertain).

Thus, the total number of HADS discoveries in the field of 300 square degrees (0.73% of the sphere) is from 18 to 21, resulting in an estimate of 2500–3000 for the expected number of HADS stars for the whole sky. This estimate should be additionally somewhat increased because some variables remain undiscovered in the corners of the fields, where the 40-cm astrograph has very large distortions.

As of November, 2017, the electronic version of the 5th edition of the General Catalogue of Variable Stars (GCVS V; Samus et al. 2017) contains 212 stars that can be considered HADS variables (note that the GCVS classification system does not explicitly contain the HADS type, and we had to check classification ourselves). Thus, very many HADS stars remain not included in the GCVS. At first glance, it seems strange; as mentioned above, we are discussing stars with variation amplitudes that are not too low. However, traditional approaches to discoveries of variable stars, their study and their classification could, indeed, fail to find HADS stars because of their short periods. Such periods are no problem for modern computers, but they are not too easy to determine without a computer, as was done in early studies.

# 5 AUTOMATED CLASSIFICATION OF THE NEW MDV STARS

Several teams are currently developing algorithms that allow automated classification of variable stars from photometric data. Such algorithms are extremely important for future work on variable stars discovered in large-scale projects, like expected discoveries from the *Gaia* space mission. Among the existing algorithms, the majority has

**Table 1** — Continued.

Notes: [1] Varies in NSVS data. [2] Varies in Catalina data. [3] From NSVS data,  $P = 48.6^{d}$ . [4] A small-amplitude variable from NSVS data,  $P = 56.6^{\text{d}}$  is not detected. [5] A small-amplitude variable from NSVS data,  $P = 5.846^{\text{d}}$ . [6] Our CCD observations confirm variability, type and period. [7] Also possible is type EW with a period twice as long. [8] Min II–Min I =  $0.58^{P}$ . [9] Double star. [10] A period that is half as short is possible. [11] Also possible is type RRC with a period that is half as short. [12] Our CCD observations confirm variability. [13] The faint component of the pair varies, and photometry from scans merges the two components. The magnitudes in Table 1 are from eye estimates for the faint component. The range from scans for combined brightness is 14.05 - 100014.40 mag. [14] Period varies? [15] Varies in ASAS-SN data. [16] NSVS data suggest  $P = 33.1^{d}$ . [17] Catalina data suggest  $P = 0.359270^{d}$ . [18] NSVS data suggest  $P = 17.0^{d}$ . [19] NSVS data suggest  $P = 37.7^{d}$ . [20] NSVS data suggest  $P = 172^{d}$ . [21] NSVS data suggest  $P = 77.3^d$ . [22] NSVS data suggest  $P = 54.3^d$ . [23]  $P = 0.236266^d$  is also possible. [24] Type EB with a period twice as long is not excluded. [25] Blazhko effect? [26] NSVS data suggest  $P = 48.8^{d}$ . [27] NSVS data suggest  $P = 33.9^{d}$ . [28]  $P = 0.412568^{d}$  is also possible. [29] Varies in NSVS data, no period. [30] From NSVS data, small amplitude,  $P = 17.25^{d}$ . [31] NSVS data suggest  $P = 143.8^{d}$ . [32] NSVS data suggest  $P = 53.4^{d}$ . [33] Also possible is an HADS type with a period that is half as short. [34] NSVS data suggest  $P = 38.3^{d}$ . [35] NSVS data suggest type SR and  $P = 34.1^{d}$ . [36] A period twice as long is possible. [37] NSVS data suggest type SR and  $P = 37.1^{d}$ . [38] X-ray source 1RXS J182915.3+323440. [39] Emission-line star StH $\alpha$ 151, M0e. [40] NSVS data suggest  $P = 43.2^{d}$ . [41] ASAS-SN data suggest type SR and  $P = 47.4^{d}$ . [42] ASAS-SN data suggest type SR and  $P = 35.9^{\text{d}}$ . [43] NSVS data suggest  $P = 34.6^{\text{d}}$ . [44] NSVS data suggest type SR and  $P = 49^{\text{d}}$ . [45]  $P = 0.292892^{\text{d}}$ is also possible.

been tested only on high-quality photometric data. Our noisy light curves are a real challenge for such programs.

By their nature, light curves are not structured since they are noisy, the number of observations per object depends on the observing strategy and they have missing values. Additional preprocessing must be done by computing statistical descriptors or features. Their mission is to reduce dimensionality and make the data uniform, which can be handled by different algorithms.

Machine learning can be divided into three broad categories: supervised learning, which utilizes labelled data to learn patterns in each class; reinforcement learning, which interacts with the environment such as sensors or a human; and unsupervised learning using just the data to learn patterns, which later can be employed to make visualizations or as inputs for another algorithm.

In their seminal work, Debosscher et al. (2007) constructed a set of 28 features. They were based on analytical fits and periods obtained using the Lomb-Scargle periodogram. They tested this set of features on a Mixture of Gaussians, Neural Networks and Support Vector Machines (SVM, Cortes & Vapnik 1995), obtaining an average precision of 70%. The work of Kim et al. (2011) found that Random Forest (RF, Breiman 2001) outperforms SVM using 11 features. Richards et al. (2011) obtained similar conclusions by including 53 features. Pichara et al. (2012) used a database that included autoregressive features for training an RF, improving previous results. The model was enhanced later by Pichara & Protopapas (2013), who employed graphical models to fill missing data while keeping the computational cost the same.

Since features do not guarantee proper classification, Mackenzie et al. (2016) applied a different approach, developing the first unsupervised feature learning algorithm. It creates a dictionary of words with fragments of the light curves to make a new representation. With them, an SVM classifier was trained, obtaining similar and even better results than the RF while reducing the computational cost significantly.

The initial light curves of the variables in the field of 104 Her were subjected to automated classification based on the RF algorithm since it proved to be the most effective approach.

We implemented the FATS features Python package (Nun et al. 2015) using only time and magnitude fields, as the data do not have uncertainty estimates for each individual measurement. Additionally, they were augmented with 2MASS (Skrutskie et al. 2006) and *WISE* (Wright et al. 2010) colors.

To train the classifier, we used stars earlier announced in the MDV program (Kolesnikova et al. 2010; Sokolovsky et al. 2014). For different reasons, we rejected 18 objects from these lists. In particular, the less represented classes were removed as the RF algorithms cannot generalize a class with a single example. The resulting classes applied for training were: EW (129 stars); LB (115); RRAB (99); EB (62); RRC (60); SR (55); EA (45); HADS (12), for a total of 577 stars.

The result was expressed as a table which listed the three top probabilities of classification, from 0% to 100%, for each variable star. We compared them to the results of our non-automated classification presented in Table 1. The comparison is based on 273 stars; two stars were added to our list of discoveries later.

For 155 stars (57%), the classification in Table 1 coincides with the most probable suggestion from the automated classification. The classification for 85 stars (31%) is that suggested automatically as the second or third option. The non-automated classification disagrees with any option from the automated classification in 12% of all cases.

A frequent case of non-automated classification agreeing with the second or third automated option is that a different type of eclipsing variables is selected. Distinguishing between the EA, EB and EW types is sometimes really somewhat tricky. In our opinion, such cases should also be considered a relative success of the automated technique.

For the stars, the automated classification was least successful (12%). We find that nine stars ( $\sim$ 3%) corresponded to classes that were not represented in the training set, which are usually the most interesting ones. The remaining 24 stars ( $\sim$ 9%) were misclassified even when the class was represented. For noisy light curves of RR Lyrae variables and most of the HADS stars, the classifier tends to decide on the eclipsing types. The SR type was often confused with LB stars. We find that the features cannot distinguish irregularity and semi-regularity as different object classes.

Some interesting cases could not be solved automatically. Thus, the beautiful RV Tauri star MDV 776 received the following type suggestions automatically: SR (probability 56%), LB (probability 43%) and EA (probability 0%). Variable-star astronomers know that variations of RV Tauri stars are indeed semiregular and that such stars used to show minima that are sharper than maxima.

We hope that further improvement in the algorithm will prevent it from missing stars that are most attractive to astrophysicists. Thus, the automated classification can provide a correct classification for a majority of all stars. Noisy data make the task more difficult (our first attempts used "cleaned" light curves and were more successful). To provide an algorithm completely satisfying to compilers of variable-star catalogs, additional work on the code and its application to noisy data are needed.

One of the possible solutions is to enhance the dataset with OGLE-III V-band variables and gradually retrain the model as new stars are detected and classified.

### 6 CONCLUSIONS

We continue our work on digitizing photographic plates of the Moscow collection and on finding new variable stars using digitized plates. In this paper, we have presented our results for the  $10^{\circ} \times 10^{\circ}$  field centered at the star 104 Her.

In total, we discovered 275 new variable stars in the field, mainly eclipsing binaries but also pulsating stars and, possibly, rotating spotted stars. This new study generally confirms our earlier finding that HADS variables are much better represented among the new discoveries than in the General Catalogue of Variable Stars.

The special feature of this study is that we have attempted automated classification of the discovered variable stars based on our photographic photometry. The results were compared to our traditional classification. In 88% of all cases, we were able to achieve good or satisfactory results; the automated classification failed in 12% of cases.

Acknowledgements The authors would like to thank the referee for very valuable suggestions that helped us to improve the manuscript.
